Cells are fusiform rods exhibiting surface periplasmic fibers, 0.5 × 4–5 µm. Motile by means of two tufts of sheathed flagella (6–12 in total) showing a bipolar distribution. Bacterial growth appears as a thin, spreading film on sheep blood agar medium after 3–5 d of incubation under microaerobic conditions. Catalase positive. Urease, alkaline phosphatase, and gamma-glutamyl transpeptidase activity is not observed. Resistant to nalidixic acid, cephalothin, sulfamethoxazole, and trimethoprim.

Pathogenicity unknown. Isolated from feces and colonic biopsies of cotton-top tamarins (*Saguinus oedipus*) suffering from chronic colitis.

The mol% G + C of the DNA is: not determined.

Deposited strain: None.

GenBank accession number (16S rRNA): AF107494.

A spiral bacterium was observed in the feces of a cat with severe diarrhea (Foley et al., 1998). Attempts to isolate the strain were unsuccessful. A eubacterial PCR assay was applied directly to DNA from the fecal sample and sequence analysis of the amplicon revealed it to be 98.3% similar to *H. canis*. The ultrastructure of the strain differed from the latter species since bipolar tufts of multiple flagella were seen, in contrast with the 1–2 bipolar flagellar arrangement of *H. canis*. These distinctions led the authors to propose the name *"H. colifelis"* for the organism observed. However, absence of a cultured strain prohibits further studies.

Deposited strain: Not yet cultured.

GenBank accession number (16S rRNA): AF142062.

Melito et al., (2001) proposed the name *"Helicobacter winghamensis"* to designate a group of seven isolates from fecal samples of humans afflicted with gastroenteritis. The strains had been recovered from samples submitted to a National Reference Laboratory in Canada from 1997 to 1999. 16S rDNA sequence analysis revealed these strains were highly related and clearly distinct from other *Helicobacter* species, including *H. canadensis* and *H. pullorum*, enteric species also associated with human gastroenteritis to which *"Helicobacter winghamensis"* bears a close ultrastructural and biochemical resemblance. The specific epithet *"winghamensis"* refers to the area in Ontario, Canada, from which the first isolate came. Although the species description conforms with minimal standards for description of new *Helicobacter* species (Dewhirst et al., 2000a), the name has not yet been validly published.

Cells are slightly curved to spiral rods, 0.3–0.6 × 2 µm. Motile by means of 1–2 bipolar unsheathed flagella. Culture on agar media containing 10% sheep blood under microaerobic conditions may result in colony morphologies ranging from single and distinct to those with a spreading appearance, depending on the individual strain. Catalase, alkaline phosphatase, and urease activity not detected. Indoxyl acetate hydrolyzed. Nitrate not reduced. Growth at 37°C but not at 42°C under microaerobic conditions. Strains differ in their susceptibility to nalidixic acid (30 µg) and cephalothin (30 µg) in disk diffusion tests.

Pathogenicity unknown. Isolated from the feces of humans with gastroenteritis.

The mol% G + C of the DNA is: not determined.

Deposited strain: NLEP 97-1090 (proposed type strain).

GenBank accession number (16S rRNA): AF246984.

An isolate from the blood culture of a 14-month old child was identified as a *Helicobacter* species by 16S rRNA gene sequence comparisons (Tee et al., 2000); its sequence most closely resembled those of *H. fennelliae* and (to a lesser extent) *H. cinaedi* strains, although the presence of a large intervening sequence (IVS) of 353 bp was noted as a striking difference. Subsequent sequence analysis of the IVS indicated a significant similarity to an IVS previously recorded in the 23S rRNA gene of *H. canis*. These IVSs were however in opposite orientations to each other. Despite the unusual characteristics of the 16S rDNA sequence of the blood culture isolate, further work is required to determine its taxonomic status as a novel species. Comparison of the available recorded phenotypic characteristics of this strain (Tee et al., 2000) with those of other helicobacters (On et al., 1996) suggests a striking similarity to *H. fennelliae*.

Cells are spiral rods (dimensions not recorded). Colonies were pinpoint, grayish-white, and hemolytic after several days microaerobic incubation on 6% blood agar; growth was enhanced in an atmosphere containing 10% H_2. Catalase, but not alkaline phosphatase or urease produced. Resistant to nalidixic acid (30 µg) in disk diffusion tests.

The mol% G + C of the DNA is: not determined.

Deposited strain: VIDRL 6606, ATCC 700956.

GenBank accession number (16S rRNA): AF237612.

Microscopic examination of pus from an abdominal abscess revealed the presence of Gram-negative fusiform rods, thereby resembling the *"Flexispira rappini"* morphotype (Han et al., 2000). By use of direct PCR examination of DNA extracted from the pus, a 16S rDNA-derived amplicon of 1668 bp was obtained. Subsequent analysis showed the enlarged product was due to an intervening sequence of ca. 200 bp and that the amplicon shared 97% identity with strains of *H. bilis* and *"F. rappini"*. Although the authors argued that their data suggested a potential new species, this assertion is weakened by current knowledge of natural 16S rRNA gene sequence diversity in helicobacters (see Taxonomic Comments above), and the microscopic resemblance of the strain to cells of extant species. Attempts to culture the strain from pus were unsuccessful.

Deposited strain: None deposited.

GenBank accession number (16S rRNA): AJ011431.

The name *"Helicobacter muricola"* was proposed by Won et al. (2002) to delineate two strains (of four isolates) recovered from the feces and ceca of the Korean wild mouse (*Mus musculus molossinus*). The specific epithet *"muricola"* refers to the murine origin of the strains. The 16S rRNA gene sequences of the two strains were identical and most similar to *H. muridarum* and *H. pullorum* (96.71–96.36% similarity respectively). Various ultrastructural and biochemical criteria distinguish *"Helicobacter muricola"* from these and other *Helicobacter* species (Won et al., 2002).

Cells are slightly curved to weakly spiral rods, 0.4–0.5 × 2–5.5 µm. Coccal forms are frequently observed. Motile by means of bipolar unsheathed flagella. Culture on agar media containing 5% sheep blood under microaerobic conditions may result in pinpoint colonies or a thin spreading film. Catalase, and urease, but not alkaline phosphatase detected. Indoxyl acetate not hydrolyzed. Nitrate reduced. Growth at 37°C but not at 42°C under microaerobic conditions. Resistant to cephalothin (30 µg) but not to nalidixic acid (30 µg) in disk diffusion tests.

Pathogenicity unknown. Isolated from the feces and ceca of the Korean wild mouse (*Mus musculus molossinus*).

The mol% G + C of the DNA is: not determined.

Deposited strain: w-06 (proposed type strain).

GenBank accession number (16S rRNA): AF264783.

In an investigation of a potential bacteriological cause of gastritis in the dolphin species *Lagenorhynchus acutus* and *Delphinus delphis*, three strains were isolated (Harper et al., 2000). All were shown to be *Helicobacter* species by use of 16S rRNA gene sequence analysis. Additional sequences resembling those derived from the above isolates were obtained by direct PCR examination of additional dolphin stomach tissue. All sequences formed a distinct, but somewhat diverse cluster with other gastric *Helicobacter* species. Although closely related, it cannot be discounted that certain sequences represent distinct species. Unlike all cultured gastric helicobacters, alkaline phosphatase activity was not detected in the dolphin isolates. Histological examination of dolphin gastric tissue revealed lesions resembling those associated with human *H. pylori* infection.

Cells are slightly spiral rods, 0.6 × 4.0 μm. Motile by means of bipolar sheathed flagella. The colonial morphology of the strains was not described. Catalase, urease, and γ-glutamyl transpeptidase, but not alkaline phosphatase produced. Indoxyl acetate not hydrolyzed. Nitrate not reduced. Growth at 37°C and at 42°C under microaerobic conditions. Susceptible to cephalothin (30 μg) but not to nalidixic acid (30 μg) in disk diffusion tests.

Pathogenicity unknown. Isolated from the glandular mucosa of the dolphin species *Lagenorhynchus acutus*. 16S rDNA sequences resembling, but distinct from these strains, were detected by PCR in gastritic stomach tissue from the dolphin species *Delphinus delphis*.

The mol% G + C of the DNA is: not determined.

Deposited strain: none.

GenBank accession number (16S rRNA): AF292377, AF292378, AF292379.

Rectal swab and gastric fluid samples were taken from each of three captive beluga whales, one of which exhibited signs of clinical illness, and assessed for the presence of helicobacters by use of culture and PCR-based methods (Harper et al., 2002). Examinations of the two healthy whales proved negative, but one isolate (MIT 00-7128) was obtained from the fecal sample of the symptomatic whale. Analysis of this isolate 16S rDNA sequence showed it to be most similar to a *Helicobacter* strain obtained from a dolphin species, *Lagenorhynchus acutus* (see Other Organisms above). Phenotypic testing of the strain revealed it could grow on 5% sheep blood agar at both 37°C and at 42°C under microaerobic conditions, produced catalase and urease, but not alkaline phosphatase, and was unable to reduce nitrate or hydrolyze indoxyl acetate. The strain proved susceptible to both cephalothin (30 μg) and nalidixic acid (30 μg) in disk diffusion tests. Culture of the gastric fluid sample of the symptomatic whale gave negative results, but PCR analysis using a *Helicobacter*-specific assay yielded an amplicon which, when sequenced, appeared distinct from that of the whale fecal strain and more similar to a distinct dolphin *Helicobacter* sequence. Restriction fragment length polymorphism analysis of *Helicobacter*-specific assay amplicons from the fecal isolate, and whale gastric fluid, indicated the respective strains were similar but not identical, since *Hha*I but not *Alu*I profiles were distinct. Both whale *Helicobacter* sequences clustered among those of gastric helicobacters.

Deposited strain: None deposited.

GenBank accession number (16S rRNA): AF455130, AF455131.

A sequence deposited in Genbank (AJ007931) refers to *"Helicobacter ulmiensis"*, a species for which no description appears to be available in international peer-reviewed journals. Independent analyses of this strain by whole-cell protein profile comparisons and by PCR-RFLP analysis respectively has identified it as a *H. hepaticus* isolate (P. Vandamme and R J. Owen, unpublished data).

Deposited strain: none deposited.

GenBank accession number (16S rRNA): AF007931.

Genus II. **Thiovulum** *Hinze 1913, 195*[AL]

Lesley A. Robertson, J. Gijs Kuenen, Bruce J. Paster, Floyd E. Dewhirst and Peter Vandamme

Thi.o′ vu.lum. Gr. n. *thios* sulfur; L. n. *ovum* egg; M.L. neut. dim. n. *Thiovulum* small sulfur egg.

Cells are round to ovoid, **5–25 μm in diameter**. **Cytoplasm is often concentrated at one end of the cell**, with the remaining space being occupied by a large vacuole. Cytoplasm normally contains **orthorhombic sulfur inclusions**, which are generally concentrated at one end and often almost filling cells completely (Fig. BXII.ε.8). The amount of sulfur present in the cells varies with the H_2S supply, and cells may be temporarily fully devoid of sulfur inclusions. The number of **greenish bodies (up to 5 μm in diameter)**, thought to be **storage material**, increases with decreasing numbers of sulfur globules (Hinze, 1913). **Cells are rapidly motile** by peritrichous flagella (Fig. BXII.ε.9; de Boer et al., 1961). Swimming **velocity of over 600 μm s^{-1}**, some of the highest recorded in the bacterial world (Garcia-Pichel, 1989). Forward movement is accompanied by rotation around the long axis. Unlike most motile bacteria, *Thiovulum* cells do swim backwards or tumble. Cells possess a **fibrillar, or antapical organelle** at the posterior end of the cell. Its function is to secrete a **slime stalk** or thread (Fig. BXII.ε.9) which is used by cells to attach to solid surfaces. No resting stages are known.

Organisms are found in freshwater and marine environments, e.g., marshes, where sulfide-containing water or mud layers are in contact with overlaying oxygen-containing water (Kuever et al., 1996).

Gram negative. Microaerophilic. No pure cultures are available. Chemolithotrophic, oxidize sulfide. Catalase negative. Multiplication is by constriction followed by fission. Cell division appeared to take place along the longitudinal axis and without any specific relation to the distribution of cell contents. The cell wall was reported to be of the normal double type comprising polysaccharides.

Type species: **Thiovulum majus** Hinze 1913, 195.

Further descriptive information

Strongly chemotactic with respect to O_2 (Fenchel and Glud, 1998). Chemotaxis with respect to H_2S may not occur (Fenchel, 1994). Cells concentrate in sharply defined, characteristic white veils or webs consisting of separate, individually moving cells held together to some extent by a loose slime matrix. These cell masses are found at the O_2/H_2S interface where both substrates occur at low concentrations (0–10 μM^{-1}) but are constantly replen-

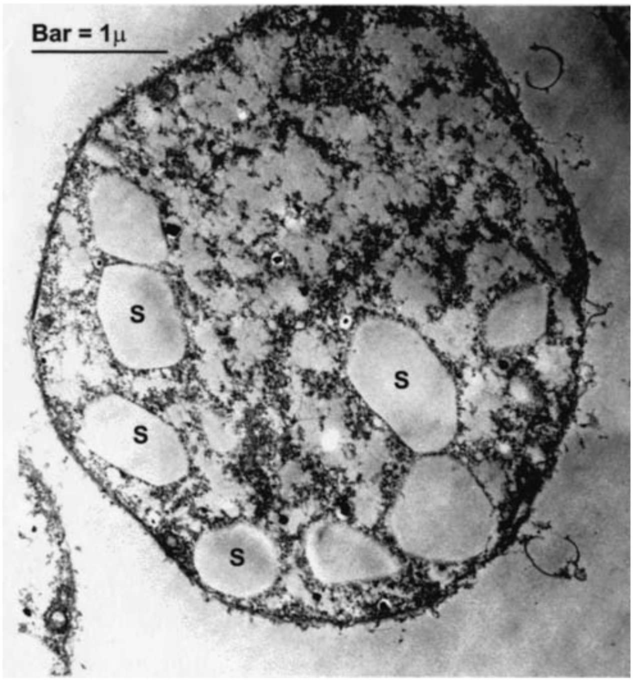

FIGURE BXII.ε.8. Ultrathin section of *Thiovulum* cell showing sulfur crystals (*S*) accumulating toward one end of the cell. (Photograph by the late Willemina E. de Boer.)

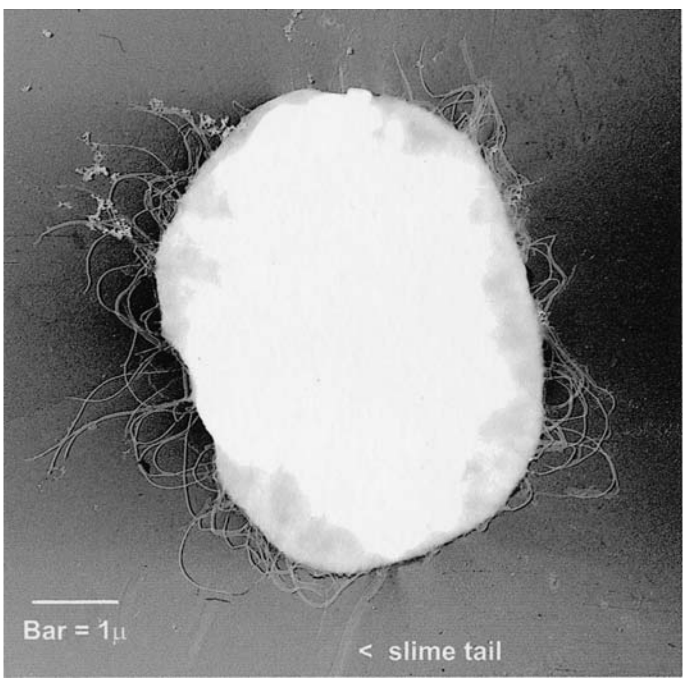

FIGURE BXII.ε.9. Platinum-shadowed *Thiovulum* cell showing flagella and the slime stalk or tail. (Photograph by the late Willemina E. de Boer.)

ished by diffusion (Jørgensen and Revsbech, 1983). *Thiovulum* veils may be as little as 200 μm thick (Bernard and Fenchel, 1995). New evidence has shown that *Thiovulum* veils also generate convective O_2 transport through the surrounding water. Oxygenated water passes down through the veil, and anoxic water is then recirculated through distinct holes in the veil, probably enhancing the rates of respiration and sulfide oxidation (Fenchel and Glud, 1998). Cells are killed by both anaerobic conditions and O_2 concentrations near air saturation values.

Although there are no pure cultures of *Thiovulum*, considerable progress has been made in the study of its physiology by means of crude laboratory enrichments (Wirsen and Jannasch, 1978; Jørgensen and Revsbech, 1983). Members of this genus may gain in importance when studies of sulfide oxidizers encountered at the deep-sea bottom around H_2S-emitting hydrothermal vents (Jannasch, 1984) have been made.

Enrichment and Isolation Procedures

There are various methods for enrichment and maintenance of *Thiovulum* from seawater, all of which are based upon the provision of a H_2S-generating system coupled to a continuous and controlled supply of dissolved oxygen (Wirsen and Jannasch, 1978; la Rivière and Schmidt, 1981). In order to exclude photosynthetic sulfur bacteria, enrichment cultures must be kept in the dark; low temperatures (<15°C) appear to be favorable.

A good example is a system consisting of a 1–10 liter jar with a layer of decaying *Ulva* on the bottom and a continuous flow of seawater entering near the bottom. The sediment provides H_2S through reduction of sulfate supplied by the seawater, which is also a continuous O_2 source. *Thiovulum* cells maintain themselves at the optimal location in the gradient thus created and, in contrast to the nonchemotactic contaminants, are not flushed out. H_2S sources other than decaying *Ulva* can be employed, such as a pure culture of sulfate-reducing bacteria fed independently and kept separate from the *Thiovulum* culture by a dialysis membrane.

Vigorously growing laboratory enrichments can be maintained by such methods for many months and can provide ample material for morphological, physiological, and phylogenetic study. Unfortunately, pure cultures of *Thiovulum* have not been obtained.

Taxonomic Comments

The names *Thiovulum majus*, *Thiovulum minus*, and *Thiovulum muelleri* have all been used to refer to *Thiovulum* cells that differed mainly in their cellular sizes and habitat (Starr and Skerman 1965; la Rivière, 1974). Currently only the name *T. majus* is used, although it is likely that there is more than one species within the genus *Thiovulum*. Comparative 16S rRNA gene sequence analysis of enriched *Thiovulum*-like cells has been achieved (Romaniuk et al., 1987; Lane et al., 1992) and phylogenetic analysis demonstrated that these unusual bacteria are closely related to the family *Helicobacteraceae*, which belongs in the *Epsilonproteobacteria* (see Fig. BXII.ε.10). To date, the closest relatives to *Thiovulum* are related only at the genus level and are species identified from 16S rRNA gene clonal analysis of bacteria from an active hydrothermal vent (Moyer et al., 1995) and epibiotic bacteria associated with the hydrothermal vent polychaete *Alvinella pompejana* (Haddad et al., 1995). In the absence of pure cultures, sequence analyses of cloned 16S rRNA genes amplified directly from environmental samples can establish the phylogenetic diversity within the genus.

Acknowledgments

Bruce J. Paster and Floyd E. Dewhirst were supported by NIH Grants DE10374 and DE11443. Peter Vandamme is indebted to the Fund for Scientific Research Vlaanderen (Belgium) for a position as a postdoctoral fellow.

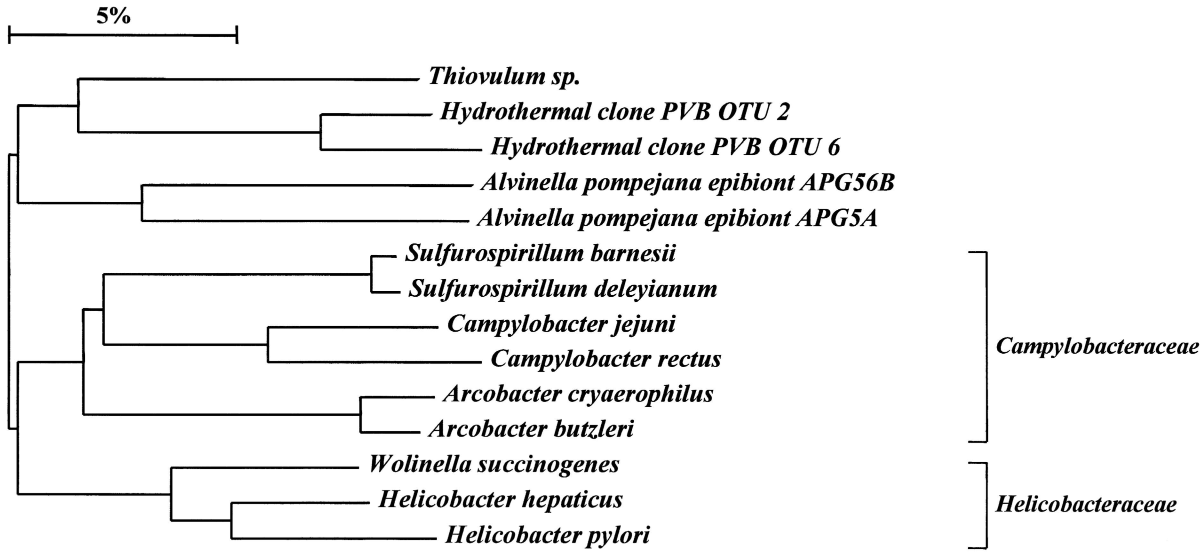

FIGURE BXII.ε.10. The phylogenetic relationships of species of the genus *Thiovulum* compared to other members of the *Epsilonproteobacteria. Thiovulum* is closely related to the family *Helicobacteraceae.* Bar = 5% difference in 16S rDNA nucleotide sequences. Due to the phylogenetic depth of *Thiovulum,* bootstrap confidence levels are not included.

List of species of the genus Thiovulum

1. **Thiovulum majus** Hinze 1913, 195[AL]
ma'jus. L. comp. adj. *major* larger.

For a description, see that of the genus.
The mol% G + C of the DNA is: not known.
Type strain: No culture isolated.
GenBank accession number (16S rRNA): M92323 (5′ end) and M92334 (3′ end).
Additional Remarks: GenBank accession numbers for operational taxonomic units (OTUs) from a hydrothermal vent: U15100–U15107.

Genus III. **Wolinella** *Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981, 439[VP]*

Achim Kröger, Oliver Klimmek, Peter Vandamme, Floyd E. Dewhirst and Bruce J. Paster

Wo.li.nel' la. M.L. ending *-ella*; M.L. fem. n. *Wolinella* named after M.J. Wolin, American bacteriologist who first isolated the type species.

Helical, curved, or straight, unbranched cells, 0.5–1.0 × 2–6 µm, with rounded or tapered ends. Endospores are not produced. Gram negative. **Rapid, darting motility** is by means of a single polar flagellum. Colonies are pale yellow opaque to gray translucent with convex, pitting, and spreading variants.

Anaerobic. **Hydrogen and formate are electron donors** and are used as energy sources. **Fumarate**, **polysulfide, nitrate**, and other compounds are used as **electron acceptors**. **Formate is oxidized to CO_2**, while **fumarate is reduced to succinate**. **Carbohydrates are not fermented** and do not support growth. **Hydrogen sulfide** is produced by polysulfide reduction. Catalase negative. The type strain was isolated from the bovine rumen.

Menaquinone-6 (2-methyl-3-farnesyl-farnesyl-1,4-naphthoquinone) and **a methyl-substituted menaquinone-6** (2, [5 or 8]-dimethyl-3-farnesyl-farnesyl-1,4-naphthoquinone) have been reported as **major respiratory quinones** (Collins and Fernandez, 1984).

There is only one member of the genus, the type species *Wolinella succinogenes.*

The mol% G + C of the DNA is: 47.

Type species: **Wolinella succinogenes** (Wolin, Wolin and Jacobs 1961) Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981, 439 (*Vibrio succinogenes* Wolin, Wolin and Jacobs 1961, 917.)

Further descriptive information

L-Asparaginase has been isolated from *W. succinogenes* (Kafkewitz and Goodman, 1974; Albanese and Kafkewitz, 1978) and from similar organisms isolated from humans (Radcliffe et al., 1979). This enzyme has been of particular interest for its potential antitumor activity. For example, asparaginase from *W. succinogenes* was shown to inhibit the growth of cultured pancreatic carcinoma cells (Wu et al., 1978).

Growth of *W. succinogenes* *W. succinogenes* can grow by anaerobic respiration with fumarate, nitrate, nitrite, N_2O, polysulfide ([S]), or DMSO as terminal electron acceptor, and formate as electron donor (reaction a–f in Table BXII.ε.6). The stoichiometry of reactions (a), (b), (c), and (e) was confirmed experimentally with growing cultures, and cell formation was shown to be proportional to substrate consumption and product formation. Polysulfide is the actual terminal electron acceptor of sulfur respiration by *W. succinogenes*, and is formed abiotically from elemental sulfur in sulfide solutions. Sulfate, thiosulfate, organic disulfides (R-S-S-R), or TMAO are not used as terminal electron acceptors. Growth is observed with fumarate, nitrate, nitrite, polysulfide, or DMSO when formate is replaced by H_2.

Fumarate can be used as the sole source of carbon during

[b]g dry cells/mol fumarate.

growth by fumarate respiration. However, growth rate and growth yield are nearly doubled with small amounts of glutamate (1% of the fumarate amount) (Bronder et al., 1982). The growth parameters with yeast extract are slightly higher than those with glutamate. Glutamate is partially incorporated into the bacterial cell mass, specifically into the amino acid residues of the glutamate family. The residual glutamate is oxidized to succinate. Succinate (or fumarate) and glutamate serve as carbon sources during growth according to reactions b–f. Acetate and glutamate are used as carbon sources when polysulfide serves as terminal electron acceptor. While sulfate is used as the source of sulfur during growth with fumarate, either H_2S or cysteine has to be supplied for growth with nitrate.

ATP synthesis The ATP required for growth is synthesized according to a mechanism similar to that of oxidative phosphorylation. An electrochemical proton potential of 160 mV is generated across the cytoplasmic membrane of *W. succinogenes* by electron transport from formate or H_2 to fumarate or polysulfide (Mell et al., 1986; Wloczyk et al., 1989). In the second step, the free energy stored in the proton potential is used for ATP synthesis from ADP and phosphate, catalyzed by ATP synthase. The ATP synthase isolated from the membrane of *W. succinogenes* is similar to those of aerobic or phototrophic bacteria (Bokranz et al., 1985).

Electron transport with fumarate The electron transport chain catalyzing fumarate reduction by formate (reaction a) or H_2 consists of fumarate reductase, menaquinone, and formate dehydrogenase or hydrogenase (Fig. BXII.ε.11). Formate dehydrogenase or hydrogenase catalyzes menaquinone reduction by formate or H_2, and fumarate reductase catalyzes menaquinol reoxidation by fumarate. The three enzymes are built according to a common principle. Each enzyme consists of two hydrophilic and one hydrophobic subunit. The hydrophobic subunits are different diheme cytochromes *b* carrying the active sites for menaquinone or menaquinol. The substrate sites are located on the larger hydrophilic subunits. The smaller hydrophilic subunits represent iron–sulfur proteins that probably mediate electron transfer between the other two subunits. The catalytic subunits of hydrogenase and formate dehydrogenase protrude into the periplasmic space, while that of fumarate reductase faces the cytoplasm. It has been suggested that the electrochemical proton potential across the membrane is generated by transmembrane electron transport (Mell et al., 1986). Reconstitution of coupled fumarate respiration was carried out in liposomes by incorporating the electron transport enzymes isolated from *W. succinogenes* (Biel et al., 2002).

The genes encoding the subunits of hydrogenase (*hydABC*) and fumarate reductase (*frdCAB*) form separate operons on the genome of *W. succinogenes* (Lauterbach et al., 1990; Dross et al., 1992). A deletion mutant lacking the *hyd* genes did not grow with H_2 and fumarate (Gross et al., 1998). When grown with formate and fumarate, the mutant did not catalyze fumarate reduction by H_2, in contrast to the wild-type strain. Growth and electron transport activity with H_2 was restored upon integration of the *hyd* genes into the genome of the deletion mutant. A deletion mutant lacking the *frd* genes did not grow with fumarate and either H_2 or formate (Simon et al., 1998). The mutant grown

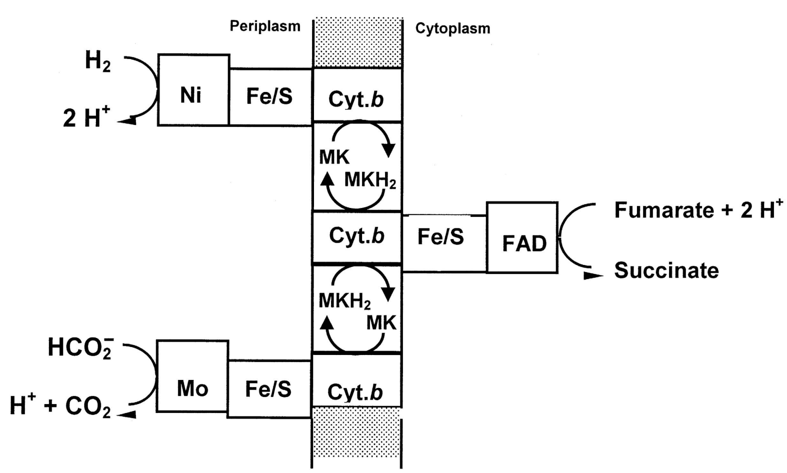

FIGURE BXII.ε.11. The electron transport system of *W. succinogenes* catalyzing fumarate reduction by H_2 or formate (Kröger et al., 1992). Hydrogenase contains nickel ion. Fumarate reductase contains covalently bound FAD. Formate dehydrogenase contains molybdenum ion. Fe/S, iron–sulfur centers; Cyt. *b*, diheme cytochrome *b*.

with nitrate as terminal electron acceptor did not catalyze fumarate reduction by H_2 or formate, in contrast to the wild-type strain. Integration of the *frd* genes into the genome of the deletion mutant caused recovery of growth and electron transport activity with fumarate. Two operons on the genome of *W. succinogenes* encode the subunits of formate dehydrogenase (Lenger et al., 1997). The operons differ in their promoter regions, but are nearly identical in their gene sequences. Deletion mutants lacking one of the operons still grow with formate and fumarate. The enzymes of the mutants appear to be identical.

Electron transport with polysulfide The electron transport chain catalyzing polysulfide reduction by H_2 or formate consists of polysulfide reductase, hydrogenase, or formate dehydrogenase (Schröder et al., 1988; Fauque et al., 1994). Hydrogenase and formate dehydrogenase are identical with the enzymes involved in fumarate reduction. The mutant lacking the *hyd* operon does not grow with H_2 and polysulfide, and growth with H_2 is restored upon insertion of the *hyd* operon into the genome of the deletion mutant (Gross et al., 1998). Polysulfide reductase is a molybdenum enzyme consisting of three different subunits (Fauque et al., 1994; Krafft et al., 1995). The catalytic subunit contains molybdenum coordinated by molybdopterin guanine dinucleotide (Jankielewicz et al., 1994). The second hydrophilic subunit is an iron–sulfur protein. The enzyme is anchored in the membrane by a hydrophobic subunit, which probably carries bound methylmenaquinone but no heme or other redox-active prosthetic groups (Dietrich and Klimmek, 2002). Electron transfer from hydrogenase to polysulfide reductase requires an intact hydrogenase cytochrome *b* (Gross et al., 1998). A deletion mutant lacking the polysulfide reductase genes (*psrABC*) does not catalyze polysulfide reduction by H_2 or formate when grown with fumarate, in contrast to the wild-type strain (Krafft et al., 1995). The deletion mutant grows with polysulfide. It forms a second polysulfide reductase that is different from the wild-type enzyme and is not present in the wild-type strain growing with polysulfide. The catalytic subunits of polysulfide reductase and formate dehydrogenase resemble those of other molybdooxidoreductases, including the formate dehydrogenase, nitrate reductase, and DMSO reductase of *Escherichia coli*.

Enrichment and Isolation Procedures

W. succinogenes was isolated from an inoculum of bovine rumen fluid after serial transfer in an anaerobic methanogenic enrichment medium containing formate, sulfide, and inorganic salts. Secondary enrichment was made in a broth medium containing formate and fumarate (Wolin et al., 1961). Additional strains of *W. succinogenes* were recently isolated (unpublished data) using the same procedure, except that the primary medium contained fumarate. These strains were virtually indistinguishable from the original Wolin strain with respect to 16S rRNA gene sequence growth with fumarate, nitrate, or polysulfide, and the specific activities of electron transport from formate to fumarate or polysulfide. The genomes of the new isolates also contain two copies of the formate dehydrogenase operon. The media and buffer used for recent isolation of *W. succinogenes* were made anoxic by alternate evacuation and flushing with N_2. Bovine rumen fluid obtained from the local slaughterhouse was passed through filter paper, and the filtrate (250 ml) was centrifuged for 15 min at 10,000 × g. The sediment was resuspended in 0.2 liter Tris-buffer (50 mM, pH 8.0, 0°C). Centrifugation was repeated and the sediment was suspended in 0.2 l medium I (50 mM Tris-chloride, 20 mM sodium acetate, 0.1 M fumaric acid, 1 mM glutamic acid, 0.1 M sodium formate, 0.25 mM $MgCl_2$, 10 mM K_2HPO_4, 0.05 mM $CaCl_2$, 5 mM $(NH_4)_2SO_4$; trace element solution SL8 (Pfennig and Trüper, 1981), 0.2 ml/l culture; the pH was adjusted to 7.6–7.8 by KOH addition, and the medium was autoclaved). This suspension was used to inoculate (5%) culture medium I. The culture was kept for 24 h at 37°C. Using 5% inoculum and the same growth conditions, the bacteria were transferred to medium II (same as medium I, except it contains 10 mM NH_4Cl and 2 mM Na_2S instead of $(NH_4)_2SO_4$, and no acetate), then to medium I, and finally to agar (1%) plates containing medium I. Plating was repeated three times.

Maintenance Procedures

Wolinella succinogenes can be maintained in the laboratory by weekly transfer on the media described above or on commercially prepared Trypticase soy agar (BBL) supplemented with 5% sheep blood. Several broth media for the cultivation of *W. succinogenes* have been described (Wolin et al., 1961; Kafkewitz, 1975). *Wolinella succinogenes* will grow in a broth medium (MFF broth) consisting of *Mycoplasma* broth supplemented with hemin (5 mg/l), sodium formate (2 g/l), and sodium fumarate (3 g/l). The organism grows at 37°C in an atmosphere of $N_2/H_2/CO_2$ (80:10:10).

For preservation by lyophilization, a dense suspension of cells harvested from surface growth on blood agar media is prepared in broth containing 5% serum and 1% glucose. Organisms can also be preserved in liquid nitrogen by placing young colonies from blood agar plates into broth supplemented with 5% DMSO, for slow freezing before final storage.

Differentiation of the genus *Wolinella* from other genera

There are only a few phenotypic criteria that differentiate *W. succinogenes* from closely related taxa, namely species of the genera *Helicobacter*, *Campylobacter*, and *Arcobacter*. *W. succinogenes* is anaerobic, and not capable of microaerophilic growth as are members of the other three genera. *W. succinogenes* is catalase negative, whereas most species of *Helicobacter* and *Arcobacter* are catalase positive. Most species of *Campylobacter* are catalase positive. *W. succinogenes* is clearly distinguished from the other genera based on 16S rRNA gene sequence comparisons (Fig. BXII.ε.12).

Taxonomic Comments

There is only one species of the genus, the type species *Wolinella succinogenes*. Tanner et al. (1981) had initially described two oral species of *Wolinella*, *W. recta*, and *W. curva*; however, 16S rRNA gene sequence analysis indicated that these two species were more closely related to campylobacters than to *W. succinogenes* (Paster and Dewhirst, 1988). These species are now described as members of the genus *Campylobacter* (Vandamme et al., 1991a). Cells are short, Gram-negative rods with a characteristic rapid darting motility. *W. succinogenes* is anaerobic and uses hydrogen and formate as electron donors. Fumarate, nitrate, and other compounds can be used as electron acceptors. Carbohydrates are not fermented and do not support growth. Hydrogen sulfide is produced. Comparative 16S rRNA gene sequence analysis has shown that *Wolinella succinogenes* falls in the family *Helicobacteraceae*, which belongs in the *Epsilonproteobacteria* (see Fig. BXII.ε.12). The closest relatives to *W. succinogenes* are species of the genus *Helicobacter*.

Acknowledgments

Peter Vandamme is indebted to the Fund for Scientific Research - Vlaanderen (Belgium) for a position as a post-doctoral research fellow. Floyd

List of species of the genus Wolinella

1. **Wolinella succinogenes** (Wolin, Wolin and Jacobs 1961) Tanner, Badger, Lai, Listgarten, Visconti and Socransky 1981, 439[VP] (*Vibrio succinogenes* Wolin, Wolin and Jacobs 1961, 917.)
suc.ci.no'ge.nes. M.L. n. *acidum succinicum* succinic acid; Gr. v. *gennaio* to produce; M.L. adj. *succinogenes* succinic acid-producing.

The characteristics are as described for the genus.

There is presently only one member of the genus, the type species *Wolinella succinogenes*. Description of species is as for the genus. Comparative 16S rRNA gene sequence analysis has shown that *W. succinogenes* falls in the family *Helicobacteraceae*, which belongs in the *Epsilonproteobacteria*. The closest relatives to *W. succinogenes* are species of the genus *Helicobacter*.

The mol% G + C of the DNA is: 47 (T_m).

Type strain: ATCC 29543, DSM 1740.

GenBank accession number (16S rRNA): M26636, M88159.

Other Organisms

Isolates resembling *W. succinogenes* have been isolated from sewage (Yoshinari, 1980) and from humans (Radcliffe et al., 1979), however no genetic information is available for these strains.

Index of Scientific Names of *Archaea* and *Bacteria*

Key to the fonts and symbols used in this index:

Nomenclature Lower case, Roman	Genera, species, and subspecies of bacteria. Every bacterial name mentioned in the *Manual* is listed in the index. Specific epithets are listed individually and also under the genus.*
CAPITALS, ROMAN:	Names of taxa higher than genus (tribes, families, orders, classes, divisions, kingdoms).
Pagination Roman:	Pages on which taxa are mentioned.
Boldface:	Indicates page on which the description of a taxon is given.†

* Infrasubspecific names, such as serovars, biovars, and pathovars, are not listed in the index.

† A description may not necessarily be given in the *Manual* for a taxon that is considered as *incertae sedis* or that is listed in an addendum or note added in proof; however, the page on which the complete citation of such a taxon is given is indicated in boldface type.
